Emergency department (ED) crowding represents an international crisis that may affect the quality and access of health care. We conducted a comprehensive PubMed search to identify articles that (1) studied causes, effects, or solutions of ED crowding; (2) described data collection and analysis methodology; (3) occurred in a general ED setting; and (4) focused on everyday crowding. Two independent reviewers identified the relevant articles by consensus. We applied a 5-level quality assessment tool to grade the methodology of each study. From 4,271 abstracts and 188 full-text articles, the reviewers identified 93 articles meeting the inclusion criteria. A total of 33 articles studied causes, 27 articles studied effects, and 40 articles studied solutions of ED crowding. Commonly studied causes of crowding included nonurgent visits, “frequent-flyer” patients, influenza season, inadequate staffing, inpatient boarding, and hospital bed shortages. Commonly studied effects of crowding included patient mortality, transport delays, treatment delays, ambulance diversion, patient elopement, and financial effect. Commonly studied solutions of crowding included additional personnel, observation units, hospital bed access, nonurgent referrals, ambulance diversion, destination control, crowding measures, and queuing theory. The results illustrated the complex, multifaceted characteristics of the ED crowding problem. Additional high-quality studies may provide valuable contributions toward better understanding and alleviating the daily crisis. This structured overview of the literature may help to identify future directions for the crowding research agenda. [Ann Emerg Med. 2008;52:126-136.]
interaction of supply and demand. We defined the scope of this review to include articles that met 4 criteria: (1) they studied causes, effects, or solutions of crowding as a primary objective; (2) they studied crowding on an empirical basis, with a description of the data collection and analysis methodology; (3) they studied crowding in the context of general emergency medicine, rather than a specialty service such as psychiatric emergency medicine; and (4) they studied everyday crowding, reflecting a focus on daily surge rather than exceptional circumstances; in other words, they did not study crowding associated with disaster events.

We identified a broad set of PubMed (MEDLINE) search terms to encompass each facet of the inclusion criteria. The search involved free text and Medical Subject Headings (MeSH) terms. We described the concept of “ED” by the following search terms: Emergency Medical Services[MeSH] OR Emergency Medicine[MeSH] OR “emergency.” We described the concept of “crowding” by the following search terms: Crowding[MeSH] OR “crowding” OR “crowded” OR “overcrowding” OR “overcrowded” OR “diversion” OR “divert” OR “congestion” OR “surge” OR “capacity” OR “crisis” OR “crises” OR “occupancy.” We queried MEDLINE on June 6, 2006, with the Boolean union of the above queries, restricting the search to English-language publications.

Study Selection

Two reviewers (N.R.H. and D.A.) independently examined the results returned by the MEDLINE search to identify potentially relevant abstracts. Articles that clearly did not meet one or more of the review criteria according to the title and abstract were not considered further. When the 2 reviewers disagreed, a consensus was reached through discussion. We retrieved full-text articles for the potentially relevant abstracts. The same 2 reviewers independently examined the full-text articles to determine which studies met all 4 of the inclusion criteria. Disagreements were again resolved through discussion to reach a final consensus set of articles that met the review criteria.

Data Collection and Processing

We used a data extraction form (Appendix E1, available online at http://www.annemergmed.com) to record information about the methods and results of each relevant article, including study design, study setting, study population, sample size, independent variables, dependent variables, and primary findings. We assigned the articles to nonexclusive groups according to whether they investigated causes, effects, or solutions of ED crowding. We attempted to represent the intentions of the original authors when assigning each article to a group. For example, an issue such as ambulance diversion may be considered a cause, effect, or solution of ED crowding, depending on the perspective of each study: it might be a cause of crowding at nearby institutions to which patients are diverted, it might be an effect of crowding at a single institution of interest, or it might be a solution of crowding by reducing the patient load. Within the groups representing causes, effects, and solutions of ED crowding, we further categorized articles according to common themes that emerged among the primary findings during the data abstraction phase.

Assessment of Study Quality

To assess the methodological quality of the studies, we applied a previously described 5-level instrument. Although it was originally developed to judge clinical trials, we applied the instrument consistently to clinical trials, descriptive studies, and surveys by using the following adaptation: Quality level 1 included prospective studies that studied a clearly defined outcome measure with a random or consecutive sample that was large enough to achieve narrow confidence intervals and diverse enough to suggest generalizability of the findings. Quality level 2 included prospective studies that were more limited in terms of sample size or generalizability. Quality level 3 included retrospective studies that otherwise would have satisfied the criteria for quality level 1 or 2. Quality level 4 included studies that sampled by convenience or other techniques that were prone to introduce bias. Quality level 5 included studies that lacked a clearly defined or validated outcome measure. We did not score articles that lacked necessary methodological details for the quality instrument.

RESULTS

The MEDLINE query returned 4,271 abstracts. The reviewers identified 188 abstracts for full-text retrieval, of which 93 articles satisfied the criteria for inclusion in the review. A flow diagram of the selection process is presented in the Figure 1. The rate of reviewer agreement during the abstract screening phase, before consensus discussion, was 93% overall, 76% among included articles, and 94% among excluded articles. The κ statistic for chance-corrected agreement between the 2 reviewers was 0.47 (95% confidence interval: 0.42 to 0.52), denoting moderate agreement.

We found that quality level 1 contained 14 articles, quality level 2 contained 12 articles, quality level 3 contained 47 articles, quality level 4 contained 10 articles, and quality level 5 contained 6 articles. Four articles were not scored because of inadequate reporting of methodology. The primary findings of all articles are summarized briefly in the following sections. The methods and results of each high-quality prospective study are described in Table 1. A total of 33 articles studied causes, 27 articles studied effects, and 40 articles studied solutions of ED crowding. This sum exceeds 93 because some articles were assigned to multiple categories as necessary.

Causes

Three general themes existed among the causes of ED crowding: input factors, throughput factors, and output factors. These themes correspond to a conceptual framework for studying ED crowding. Input factors reflected sources and aspects of patient inflow. Throughput factors reflected...
bottlenecks within the ED. Output factors reflected bottlenecks in other parts of the health care system that might affect the ED. The commonly studied causes of crowding are summarized in Table 2.

**Input factors.** We identified nonurgent visits, so-called frequent-flyer patients, and the influenza season to be commonly studied input factors that may cause crowding.

Four articles considered nonurgent visits: Three studies found that low-acuity ED patients frequently sought nonurgent care in the ED, and their reasons for doing so included insufficient or untimely access to primary care.\(^{19,21}\) However, one analysis suggested that visits by patients with nonurgent complaints were not associated with the most severe crowding at large hospitals.\(^{22}\)

Two articles studied frequent-flyer patients: One report found that frequent visitors, defined by 4 or more annual visits, accounted for 14% of the total ED visits.\(^{23}\) Moreover, these patients generally did not have urgent complaints and exhibited Andersen's\(^{24}\) “need factors” for health care. A similar report found that the 500 most frequent users of one ED accounted for 8% of total visits, and 29% of these visits might have been appropriate for primary care.\(^{25}\)

Three articles investigated the influenza season: Los Angeles County hospitals recorded a 4- to 7-fold increase in ambulance diversion during the peak 4 weeks of flu season compared with other times of the year.\(^{26}\) In Toronto, every 10 local cases of flu resulted in a 1.5% increase in the fraction of ED visitors who were elderly flu patients.\(^{27}\) The same group in Toronto calculated that every 100 local cases of flu resulted in an increase of 2.5 hours per week of ambulance diversion.\(^{28}\)

Four articles examined other aspects of input factors:

Stockholm experienced a 21% increase in ED visits during a 4-year span, far exceeding the population growth of 4.5% during the same period; the authors attributed this to 2 hospital closures that caused the ED to become more responsible for primary care delivery.\(^{29}\) One study estimated that excess patient volume prompted 71% of ambulance diversion episodes, and excess patient acuity prompted 15% of ambulance diversion episodes.\(^{30}\) Although recently discharged inpatients accounted for just 3% of total visits to one ED, they had longer lengths of stay and more frequent hospital admissions than other patients.\(^{31}\) California EDs that were located in neighborhoods of lower socioeconomic status had increased waiting times, estimated to be 10 minutes longer per $10,000 reduction in per capita income.\(^{32}\)

**Output factors.** We identified inadequate staffing to be a commonly studied throughput factor that may cause crowding.

Three articles discussed inadequate staffing: A point prevalence study of crowding found that the average nurse was caring for 4 patients simultaneously, and the average physician was caring for 10 patients simultaneously.\(^{33}\) A study in California showed that lower staffing levels of physicians and triage nurses predisposed patients to wait longer for care.\(^{34}\) By contrast, a time series analysis indicated that, after controlling for other factors, ambulance diversion was not associated with physician and nurse staffing levels.\(^{34}\)

Three articles discussed other aspects of throughput factors: During a 9-year period, the number of California EDs decreased by 12%, whereas the number of ED beds increased by 16%.\(^{35}\) This increase may not have been sufficient, considering that the number of visits and critical visits per ED increased by 27% and 59%, respectively, during the same period. The training background of the attending physician in charge of an ED has been independently associated with patients leaving without being seen.\(^{36}\) The use of ancillary services, including computed tomographic (CT) scanning and other procedures, prolonged the ED length of stay among surgical critical care patients.\(^{37}\)

Five articles studied inpatient boarding: One study found that half of EDs in the United States reported extended boarding times for patients in the ED.\(^{38}\) A point prevalence study found that 22% of all ED patients were boarding at one time.\(^{33}\) One academic ED delivered 154 patient-days of care to critically ill patients during a 1-year period.\(^{39}\) Patients experiencing access block, defined by boarding time exceeding 8 hours, was associated with increased diversion, waiting times, and occupancy level in an Australian ED.\(^{40}\) A time series analysis showed that the number of boarding patients was independently associated with the frequency of ambulance diversion.\(^{34}\)

Six articles examined hospital bed shortages: A study of English accident and emergency trusts found a strong

correlation between ED treatment time and hospital occupancy. A period of widespread hospital restructuring in Toronto independently increased the rate of severe crowding from 0.5% to 6% of the time. Length of stay in one ED increased substantially when the hospital occupancy levels exceeded 90%. A survey of Korean EDs linked high hospital occupancy levels to ED crowding. A study in Portland found that a decrease in the number of hospital beds was strongly associated with an increase in ambulance diversion. Another study estimated that a hospital closure would affect the nearest ED by increasing ambulance diversion by 56 hours per month for 4 months.

Additional themes. Five surveys and interviews identified factors that health care providers and other stakeholders perceive to be important causes of ED crowding: increasing patient volume and acuity, shortages of treatment areas, shortages of nursing staff, delays in ancillary services, boarding inpatients, and hospital bed shortages.

Effects

Four general themes existed among the effects of ED crowding: adverse outcomes, reduced quality, impaired access, and provider losses. Adverse outcomes reflected health-related patient endpoints. Reduced quality reflected benchmarks of the care delivery process. Impaired access reflected the ability of patients to receive timely care at their preferred institutions. Provider losses reflected consequences borne by the health care system itself. The commonly studied effects of crowding are summarized in Table 3.

*READI, Real-time Emergency Analysis of Demand Indicators; NEDOCS, National Emergency Department Overcrowding Scale.*
transport time increased by 11%.59

Four articles investigated treatment delays: Patients who arrived at one ED during crowded periods waited 30 minutes longer for an ED bed.60 Crowding was associated with increased door-to-needle time for patients with suspected myocardial infarction.61 High ED occupancy levels were associated with delayed pain assessment and lower likelihood of pain documentation among hip fracture patients.62 A trial with negative results found no increase in the time to head CT among patients with suspected stroke when a trauma evaluation occurred simultaneously.63

**Impaired access.** We identified ambulance diversion and patient elopement to be commonly studied effects of crowding pertaining to impaired access.

Two articles focused on ambulance diversion: A national survey found that approximately 501,000 ambulance diversions occurred in the United States during 1 year, and approximately 70% of these were from large EDs.64 A point-prevalence study of ED crowding found that 11% of US EDs were simultaneously diverting ambulances.33

Six articles characterized patient elopement: Patients were more likely to leave without being seen when ED occupancy exceeded 100% of the total capacity.36 In one study, the rate of patients leaving without being seen was closely correlated with waiting times.65 The rate of patients leaving one ED without being seen correlated well with a crowding regression model.56

Among patients who left without being seen, 46% needed urgent medical attention, and 11% were hospitalized within a week.67 Patients frequently cited long waiting times as a reason for leaving without being seen, and 60% of them sought other medical care within a week.68 Patients who left the ED without being seen were twice as likely to report worsened health problems.69

**Provider losses.** We identified financial effect to be a commonly studied provider loss of crowding.

Two articles calculated financial effect: One study estimated that the hospital lost $204 in potential revenue per patient with an extended boarding time.70 Another study found that patients who boarded in the ED longer than a day also stayed in the hospital longer, increasing costs by an estimated $6.8 million during 3 years.71

Two articles considered other aspects of provider losses: A study found that during 1 in 8 patient transports, the ambulance could not unload the patient promptly at the ED, putting it out of service for 15 minutes or more.72 A survey of Canadian emergency physicians found that job dissatisfaction was closely related to the perceived scarcity of resources.73

**Additional themes.** Three surveys identified outcomes that ED directors perceive to be major effects of crowding: death, delayed care, unnecessary procedures, and extended pain.47-49

**Solutions**

Three general themes existed among the solutions of ED crowding: increased resources, demand management, and operations research. Increased resources reflected the deployment of additional physical, personnel, and supporting resources. Demand management reflected methods to redistribute patients or encourage appropriate utilization. Operations research reflected crowding measures and offline change management techniques. The commonly studied solutions of crowding are summarized in Table 4.

**Increased resources.** We identified additional personnel, observation units, and hospital bed access to be commonly studied solutions of crowding involving increased resources.

Three articles studied additional personnel: One described a permanent increase in the number of physicians during a busy shift, reducing the outpatient length of stay by 35 minutes.74 A rural hospital, which previously did not have an attending physician present during the night shift, found that the presence of an attending physician improved several throughput measures of ED crowding.75 One hospital activated reserve personnel as needed during the viral epidemic season, reducing the waiting time by 15 minutes and the rate of patients leaving without being seen by 37%.76

Four articles investigated observation units: One short-stay medical unit reduced the length of stay for outpatients with chest pain and asthma exacerbation.77 Another study found that an ED-managed acute care unit decreased ambulance diversion by 40% and halved the rate of patients leaving without being seen.78 A hospital reported that the addition of an acute medical unit reduced the median number of boarding patients from 14 to 8 during a 2-year period.79 One study proposed a hybrid observation unit, which was designed to use resources effectively and substantially decreased the length of stay for scheduled procedure patients.80

Two articles considered hospital bed access: After increasing the number of critical care beds from 47 to 67, ambulance diversion at one hospital decreased by 66%.81 A natural experiment resulting from a period of industrial action, leading to improved hospital bed access for an ED, resulted in significant decreases in occupancy levels and waiting times.82

Two articles examined other aspects of increased resources: One study increased both space and staffing through an ED reorganization, which resulted in the improvement of several crowding outcomes.83 Another study attempted to reduce the potential bottleneck of ancillary services by implementing point-

of-care laboratory testing, which decreased the length of stay by 41 minutes.84

**Demand management.** We identified nonurgent referrals, ambulance diversion, and destination control to be commonly studied solutions of crowding involving demand management.

Four studies tested nonurgent referrals: A survey of ED patients found that 38% would swap their ED visit for a primary care appointment within 72 hours.99 A randomized, controlled trial focused on 3 common symptom complexes and found that they may be deferred for next-day primary care without worsening self-reported health status on follow-up.85 When following up nonurgent patients who were triaged to receive care elsewhere, one group found that there were no major adverse outcomes, and 42% of the patients received same-day care elsewhere.86 A similar study found that 94% of nonurgent patients who were referred to community-based care reported that their condition was better or unchanged.87

Five studies investigated ambulance diversion: By one calculation, ambulance diversion decreased the rate of ambulance arrivals by 30% to 50%.88 A similar calculation found that “red-alert” ambulance diversion reduced the arrival rate by 0.4 per hour.90 When one hospital committed to avoiding ambulance diversion for 1 week, the need for diversion at a nearby hospital was almost eliminated.90 Standardized diversion criteria in Sacramento, targeted to decrease “round-robin” crowding, reduced the rate of ambulance diversion by 74% despite increased patient volume.91 San Diego implemented a standardized policy for initiating ambulance diversion among all local hospitals and reduced ambulance diversion by 75%.92

Two studies proposed destination control: The use of Internet-accessible operating information to redistribute ambulances reduced the need for diversion from 1,788 hours to 1,138 hours in one network.93 Another study described a physician-directed ambulance destination control initiative that reduced diversion by 41%.94

Three studies considered other aspects of demand management: A trial of paramedic-initiated nontransport found that 2.4% of nontransported pediatric patients were later admitted to the hospital.95 Three social interventions designed for frequent visitors, which included education and counseling, were associated with decreased ED utilization.96 Another study targeted frequent users with case management interventions, but the rate of ED utilization was unchanged.97

**Operations research.** The studies within the operations research theme did not describe direct solutions to ED crowding; however, they proposed to support solutions through improved business intelligence. We identified crowding measures and queuing theory to be commonly studied solutions to crowding according to operations research.

Eight studies described crowding measures: The Emergency Department Work Index (EDWIN) associated well with ambulance diversion and less well with secondary outcome measures at its institution of origin.98 The National Emergency Department Overcrowding Scale (NEDOCS) explained 49% of the variation in physician and nurse assessments of crowding.99 The Real-time Emergency Analysis of Demand Indicators were designed for real-time monitoring of ED operations, although they did not correlate with providers’ opinions on crowding.100 The Work Score predicted ambulance diversion at its institution of origin with area under the receiver operating characteristic curve of 0.89.101 A comparative validation, which used staff assessments of crowding as the outcome, estimated the area under the receiver operating characteristic curve of the EDWIN to be 0.80 and of the NEDOCS to be 0.83.102 However, an external validation of the NEDOCS in Australia concluded that it was not useful, according to Bland-Altman and k statistics.103 A sampling form consisting of 7 operational measures was shown to correlate well with staff assessments of crowding.104 A panel of experts described 38 consensus operational measures that may be used to assess crowding levels.105

Two studies used queuing theory: One group illustrated the ability of discrete event simulation to model ED operations, and they tested its applicability by analyzing a proposed triage scheme.106 Another study described a discrete event simulation and studied the effects of physician utilization on patient waiting times.107

**Additional themes.** Five studies described multifaceted administrative interventions that could not be classified separately: A broad intervention consisting of 51 actions reduced ED length of stay and ambulance diversion in Melbourne.108 One network deployed several interventions, tuned for the individual needs of 4 hospitals, and reduced the amount of ambulance diversion by 25% and 34% in consecutive years.109 A group of hospitals in Rochester deployed several interventions, and they reported that the most effective interventions occurred outside the ED.110 Another study reported interventions, including more physicians, improved ancillary services, and changes in hospital policy, that reduced length of stay by half.111 One hospital deployed a multipronged intervention, which involved a short-stay unit, additional physicians, and an early warning system, to deal with holiday demand surges.112

**LIMITATIONS**

This study has a number of limitations that merit discussion. First, we may not have captured every article that studied causes, effects, and solutions of ED crowding. We limited the search to English-language articles, so any relevant articles published in foreign languages were not included. We avoided searching the grey literature with a general purpose internet query, and we did not hand-search the references of included articles. If used, these 2 techniques might have impaired the reproducibility of our review. We searched a single database; moreover, it is possible that our search terms did not capture all aspects of the topic. The MeSH vocabulary contains a single term related to crowding, so we supplemented the search with a large set of free-text keywords. We attempted to minimize the likelihood of missed articles by applying a broad search strategy.
We also used a conservative approach during the abstract screening phase, retrieving the full-text articles for all abstracts that could not be clearly excluded. The moderate $\kappa$ value may be explained because one author was more conservative than the other in marking abstracts for full-text retrieval. This issue was identified and resolved during the consensus discussion. We believe our methodology captured the majority of pertinent articles.

Second, the diversity of methodology, outcome measures, and reporting among the original articles rendered aspects of this review difficult. We attempted to describe the primary findings of each study as consistently as possible, noting the effect sizes of each study when feasible and in other cases describing the nature of the findings in more qualitative terms. In some cases, our descriptions were limited according to the reporting of the original articles. The brief summaries that we provide do not capture the full complexity of each study, so our review is intended to guide interested readers to the original cited articles. We did not conduct a formal meta-analysis, because of the breadth of study designs and endpoints considered. We refrain from making strong conclusions about which factors are most important because these would be based primarily on judgment rather than numeric inference.

Third, the classification of studies into groups and themes was partly subjective, so objections may be made regarding how particular articles were categorized. We acknowledge that there may be no clearly correct taxonomy for grouping this diverse set of articles. For instance, measurement tools and queuing models would not reduce ED crowding unless paired with an intervention plan. Regardless, we have classified these articles as solutions, insofar as the original authors intended their research to support crowding interventions. Our intention in using this trichotomy of causes, effects, and solutions was to provide a structured overview of the relevant literature, which we hope benefits the reader.

DISCUSSION

A substantial body of literature exists describing the causes, effects, and solutions of ED crowding. The major themes among the causes of crowding included nonurgent visits, frequent-flyer patients, influenza season, inadequate staffing, inpatient boarding, and hospital bed shortages. The major themes among the effects of crowding included patient mortality, transport delays, treatment delays, ambulance diversion, patient elopement, and financial effect. The major themes among the solutions of crowding included additional personnel, observation units, hospital bed access, nonurgent referrals, ambulance diversion, destination control, crowding measures, and queuing theory.

The quality instrument that we used indicated that a large number of high-quality articles have been published about ED crowding. We identified a total of 26 prospective studies and 47 retrospective studies that met the criteria for the 3 highest quality levels. We noted a scarcity of randomized controlled trials in this review, perhaps because many ED operational changes involve the entire department, rather than individual patients who may be randomized to experimental and control groups. We believe that the crowding literature would benefit from more randomized controlled trials examining patient-focused interventions.

Although several studies investigated nonurgent and frequent-flyer visits, relatively little evidence suggests they independently cause ED crowding. More evidence is available to identify inpatient boarding and other hospital-related factors as causes of ED crowding. These studies corroborate with successful interventions that reduced crowding by altering the operation of hospital and community services other than the ED.

The results suggest that standard operations management tools, such as queuing theory, have only recently been applied in an effort to improve ED patient flow. We are aware of few previous reports describing such applications in the ED setting. By contrast, these tools were adopted much earlier by industries like airlines and manufacturing. This lag is analogous to the gap between basic science and clinical science, which translational research aims to address. A result of queuing theory states that a system with varying inputs and fixed capacity will become congested for transient periods. By consequence, permanent increases in resources may be neither efficient nor adequate to address crowding, given the fluctuating demand. The review includes 1 study demonstrating the feasibility of deploying additional resources on demand to alleviate ED crowding. We believe that the crowding literature would benefit from studies that apply standard management research techniques to ED operations and investigate ways to alter resource availability dynamically according to demand.

When considered as a whole, the body of literature demonstrates that ED crowding is a local manifestation of a systemic disease. The causes of ED crowding involve a complex network of interwoven processes ranging from hospital workflow to viral epidemics. The effects of ED crowding are numerous and adverse. Various targeted solutions to crowding have been shown to be effective, and further studies may demonstrate new innovations. This broad overview of the current research may help to inform the future research agenda and, subsequently, to protect the fragile safety net of the health care system.
